its current shortcomings. At the same time, however, MySQL is moving ahead at the speed of light.

The case for mSQL may depend on the tools you are using. Because mSQL has been around longer, you may find more luck locating a tool that supports your specific needs. For example, only mSQL had a JDBC 2.0 compliant JDBC driver for Java database access at the time of this book’s publication. Certainly this situation will have changed by the time you read this book. Nevertheless, you need to consider issues such as that when you decide which database to use.

No matter which database you use, you will be a winner. Both database engines are faster than any other choice you will make. Both database engines are perfect for mid-range database needs. For an objective comparison of these two databases with each other or any other database, we recommend you visit http://www.mysql.com/crash-me-choose.html. It is on the MySQL home page, but its criteria are openly verifiable and it is very well done.

Database Design

Once you install your DBMS software on your computer, it can be very tempting to just jump right into creating a database without much thought or planning. As with any software development, this kind of ad hoc approach works with only the simplest of problems. If you expect your database to support any kind of complexity, some planning and design will definitely save you time in the long run. You will need to take a look at what details are important to good database design.

Database Design

Suppose you have a large collection of compact discs and you want to create a database to track them. The first step is to determine what the data that you are going to store is about. One good way to start is to think about why you want to store the data in the first place. In our case, we most likely want to be able to look up CDs by artist, title, and song. Since we want to look up those items, we know they must be included in the database. In addition, it is often useful to simply list items that should be tracked. One possible list might include: CD title, record label, band name, song title. As a starting point, we will store the data in the table shown in Table 2-1.

Table 2-1. A CD Database Made Up of a Single Table

<table>
<thead>
<tr>
<th>Band Name</th>
<th>CD Title</th>
<th>Record Label</th>
<th>Songs</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stevie Wonder</td>
<td>Talking Book</td>
<td>Motown</td>
<td>You Are the Sunshine of My Life, Maybe Your Baby, Superstition, . . .</td>
</tr>
<tr>
<td>Miles Davis Quintet</td>
<td>Miles Smiles</td>
<td>Columbia</td>
<td>Orbits, Circle, . . .</td>
</tr>
<tr>
<td>Wayne Shorter</td>
<td>Speak No Evil</td>
<td>Blue Note</td>
<td>Witch Hunt, Fee-Fi-Fo-Fum</td>
</tr>
</tbody>
</table>
Table 2-1. A CD Database Made Up of a Single Table (continued)

<table>
<thead>
<tr>
<th>Band Name</th>
<th>CD Title</th>
<th>Record Label</th>
<th>Songs</th>
</tr>
</thead>
<tbody>
<tr>
<td>Herbie Hancock</td>
<td>Headhunters</td>
<td>Columbia</td>
<td>Chameleon, Watermelon, Man, . . .</td>
</tr>
<tr>
<td>Herbie Hancock</td>
<td>Maiden Voyage</td>
<td>Blue Note</td>
<td>Maiden Voyage</td>
</tr>
</tbody>
</table>

(For brevity’s sake, we have left out most of the songs.) At first glance, this table seems like it will meet our needs since we are storing all of the data we need. Upon closer inspection, however, we find several problems. Take the example of Herbie Hancock. “Band Name” is repeated twice: once for each CD. This repetition is a problem for several reasons. First, when entering data in the database, we end up typing the same name over and over. Second, and more important, if any of the data changes, we have to update it in multiple places. For example, what if “Herbie” were misspelled? We would have to update the data in each of the two rows. The same problem would occur if the name Herbie Hancock changes in the future (à la Jefferson Airplane or John Cougar). As we add more Herbie Hancock CDs to our collection, we add to the amount of effort required to maintain data consistency.

Another problem with the single CD table lies in the way it stores songs. We are storing them in the CD table as a list of songs in a single column. We will run into all sorts of problems if we want to use this data meaningfully. Imagine having to enter and maintain that list. And what if we want to store the length of the songs as well? What if we want to perform a search by song title? It quickly becomes clear that storing the songs in this fashion is undesirable.

This is where database design comes into play. One of the main purposes of database design is to eliminate redundancy from the database. To accomplish this task, we use a technique called normalization. Before we start with normalization, let’s start with some fundamental relational database concepts. A data model is a diagram that illustrates your database design. It is made up of three main elements: entities, attributes, and relationships. For now, let’s focus on entities and attributes; we will take a look at relationships later.

**Database Entities**

An entity is a thing or object of importance about which data must be captured. All “things” are not entities, only those things about which you want to capture information. Information about an entity is captured in the form of attributes and/or relationships. If something is a candidate for being an entity and it has no attributes or relationships, it is not really an entity. Database entities appear in a data model as a box with a title. The title is the name of the entity.

**Entity Attributes**

An attribute describes information about an entity that must be captured. Each entity has zero or more attributes that describe it, and each attribute describes exactly one entity. Each entity instance (row in the table) has exactly one value, possibly NULL, for each of its attributes. An attribute value can be numeric, a character string, date, time, or some other basic data value. In the first step of database design, logical data modeling, we do not worry about how the attributes will be stored.

NULL provides the basis for the problem of dealing with missing information. It is specifically used for the case in which you lack a certain piece of information. As an example, consider the situation where a CD does not list the song lengths of each of its tracks. Each song has a length, but you cannot tell from the case what that length is. You do not want to store the length as zero, since that would be incorrect. Instead, you store the length as NULL. If you are thinking you could store it as zero and use zero to mean “unknown,” you are falling into one of the same traps that led to one of the Y2K problems. Not only did old systems store years as two digits, but they often gave a special meaning to 99-99.

Our example database refers to a number of things: the CD, the CD title, the band name, the songs, and the record label. Which of these are entities and which are attributes?

**Data Model**

Notice that we capture several pieces of data (CD title, band name, etc.) about each CD, and we absolutely cannot describe a CD without those items. CD is therefore one of those things we want to capture data about and is likely an entity. To start a data model, we will diagram it as an entity. Figure 2-1 shows our sole entity in a data model.
By common entity naming conventions, an entity name must be singular. We therefore call the table where we store CDs “CD” and not “CDs.” We use this convention because each entity names an instance. For example, the “San Francisco 49ers” is an instance of “Football Team,” not “Football Teams.”

At first glance, it appears that the rest of the database describes a CD. This would indicate that they are attributes of CD. Figure 2-2 adds them to the CD entity in Figure 2-1. In a data model, attributes appear as names listed in their entity’s box.

![](image1)

Figure 2-2. The CD entity with its attributes

This diagram is simple, but we are not done yet. In fact, we have only just begun. Earlier, we discussed how the purpose of data modeling is to eliminate redundancy using a technique called normalization. We have a nice diagram for our database, but we have not gotten rid of the redundancy as we set out to do. It is now time to normalize our database.

**Normalization**

E.F. Codd, then a researcher for IBM, first presented the concept of database normalization in several important papers written in the 1970s. The aim of normalization remains the same today: to eradicate certain undesirable characteristics from a database design. Specifically, the goal is to remove certain kinds of data redundancy and therefore avoid update anomalies. Update anomalies are difficulties with the insert, update, and delete operations on a database due to the data structure. Normalization additionally aids in the production of a design that is a high-quality representation of the real world, thus normalization increases the clarity of the data model.

As an example, say we misspelled “Herbie Hancock” in our database and we want to update it. We would have to visit each CD by Herbie Hancock and fix the artist’s name. If the updates are controlled by an application which enables us to edit only one record at a time, we end up having to edit many rows. It would be much more desirable to have the name “Herbie Hancock” stored only once so we have to maintain it in just one place.

**First Normal Form (1NF)**

The general concept of normalization is broken up into several “normal forms.” An entity is said to be in the first normal form when all attributes are single-valued. To apply the first normal form to an entity, we have to verify that each attribute in the entity has a single value for each instance of the entity. If any attribute has repeating values, it is not in 1NF.

A quick look back at our database reveals that we have repeating values in the Songs attribute, so the CD is clearly not in 1NF. To remedy this problem, an entity with repeating values indicates that we have missed at least one other entity. One way to discover other entities is to look at each attribute and ask the question “What thing does this describe?”

What does Song describe? It lists the songs on the CD. So Song is another “thing” that we capture data about and is probably an entity. We will add it to our diagram and give it a Song Name attribute. To complete the Song entity, we need to ask if there is more about a Song that we would like to capture. We identified earlier song length as something we might want to capture. Figure 2-3 shows the new data model.

![](image2)

Figure 2-3. A data model with CD and Song entities

Now that the Song Name and Song Length are attributes in a Song entity, we have a data model with two entities in 1NF. None of their attributes contain multiple values. Unfortunately, we have not shown any way of relating a CD to a Song.

**The Unique Identifier**

Before discussing relationships, we need to impose one more rule on entities. Each entity must have a unique identifier—we’ll call it the ID. An ID is an attribute of an entity that meets the following rules:

- It is unique across all instances of the entity.
- It has a non-NULL value for each instance of the entity, for the entire lifetime of the instance.
- It has a value that never changes for the entire lifetime of the instance.
The ID is very important because it gives us a way to know which instance of an entity we are dealing with. Identifier selection is critical because it is also used to model relationships. If, after you've selected an ID for an entity, you find that it doesn't meet one of the above rules, this could affect your entire data model.

Novice data modelers often make the mistake of choosing attributes that should not be identifiers and making them identifiers. If, for example, you have a Person entity, it might be tempting to use the Name attribute as the identifier because all people have a name and that name never changes. But what if a person marries? What if the person decides to legally change his name? What if you misspelled the name when you first entered it? If any of these events causes a name change, the third rule of identifiers is violated. Worse, is a name really ever unique? Unless you can guarantee with 100% certainty that the Name is unique, you will be violating the first rule. Finally, you do know that all Person instances have non-NULL names. But are you certain that you will always know the name of a Person when you first enter information about them in the database? Depending on your application processes, you may not know the name of a Person when a record is first created. The lesson to be learned is that there are many problems with taking a non-identifying attribute and making it one.

The solution to the identifier problem is to invent an identifying attribute that has no other meaning except to serve as an identifying attribute. Because this attribute is invented and completely unrelated to the entity, we have full control over it and guarantee that it meets the rules of unique identifiers. Figure 2-4 adds invented ID attributes to each of our entities. A unique identifier is diagrammed as an underlined attribute.

![CD and Song entities with their unique identifiers](image)

**Figure 2-4. The CD and Song entities with their unique identifiers**

### Relationships

The identifiers in our entities enable us to model their relationships. A relationship describes a binary association between two entities. A relationship may also exist between an entity and itself. Such a relationship is called a recursive relationship.

Each entity within a relationship describes and is described by the other. Each side of the relationship has two components: a name and a degree.

Each side of the relationship has a name that describes the relationship. Take two hypothetical entities, an Employee and a Department. One possible relationship between the two is that an Employee is "assigned to" a Department. That Department is "responsible for" an Employee. The Employee side of the relationship is thus named "assigned to" and the Department side "responsible for."

Degree, also referred to as cardinality, states how many instances of the describing entity must describe one instance of the described entity. Degree is expressed using two different values: "one and only one" (1) and "one or many" (M). An employee is assigned to one department at a time, so Employee has a one and only one relationship with Department. In the other direction, a department is responsible for many employees. We therefore say Department has a "one or many" relationship with Employee. As a result a Department could have exactly one Employee.

It is sometimes helpful to express a relationship verbally. One way of doing this is to plug the various components of a direction of the relationship into this formula:

```
entity1 has [one and only one | one or many] entity2
```

Using this formula, Employee and Department would be expressed like so:

Each Employee must be assigned to one and only one Department.

Each Department may be responsible for one or many Employees.

We can use this formula to describe the entities in our data model. A CD contains one or many Songs and a Song is contained on one and only one CD. In our data model, this relationship can be shown by drawing a line between the two entities. Degree is expressed with a straight line for "one and only one" relationships or "crow's feet" for "one or many" relationships. Figure 2-5 illustrates these conventions.

![Anatomy of a relationship](image)

**Figure 2-5. Anatomy of a relationship**
How does this apply to the relationship between Song and CD in reality, a Song can be contained on many CDs, but we ignore this for the purposes of this example. Figure 2-6 shows the data model with the relationships in place.

![Figure 2-6. CD-Song relationship](image)

With these relationships firmly in place, we can go back to the normalization process and improve upon the design. So far, we have normalized repeating song values into a new entity and modeled the relationship between it and the CD entity.

**Second Normal Form (2NF)**

An entity is said to be in the second normal form if it is already in 1NF and all nonidentifying attributes are dependent on the entity’s entire unique identifier. If any attribute is not dependent entirely on the entity’s unique identifier, that attribute has been misplaced and must be removed. Normalize these attributes either by finding the entity where it belongs or by creating an additional entity where the attribute should be placed.

In our example, “Herbie Hancock” is the Band Name for two different CDs. This fact illustrates that Band Name is not entirely dependent on CD ID. This duplication is a problem because if, for example, we had misspelled “Herbie Hancock,” we would have to update the value in multiple places. We thus have a sign that Band Name should be part of a new entity with some relationship to CD. As before, we resolve this problem by asking the question: “What does a band name describe? It describes a band, or more generally, an artist. Artist is yet another thing we are capturing data about and is therefore probably an entity. We will add it to our diagram with Band Name as an attribute. Since all artists may not be bands, we will rename the attribute Artist Name. Figure 2-7 shows the new state of the model.

![Figure 2-7. The data model with the new Artist entity](image)

Of course, the relationships for the new Artist table are missing. We know that each Artist has one or many CDs. Each CD could have one or many Artists. We model this in Figure 2-8.

We originally had the Band Name attribute in the CD entity. It thus seemed natural to make Artist directly related to CD. But is this really correct? On closer inspection, it would seem that there should be a direct relationship between an Artist and a Song. Each Artist has one or more Songs. Each Song is performed by one and only one Artist. The true relationship appears in Figure 2-9.

Not only does this make more sense than a relationship between Artist and CD, but it also addresses the issue of compilation CDs.

**Kinds of Relationships**

When modeling the relationship between entities, it is important to determine both directions of the relationship. After both sides of the relationship have been determined, we end up with three main kinds of relationships. If both sides of the relationship have a degree of one and only one, the relationship is called a “one-to-one” or “1-to-1” relationship. As we will find out later, one-to-one relationships are rare. We do not have one in our data model.
A one-to-one relationship may imply that two entities are really the same entity. If they do turn out to be the same entity, they should be folded into a single entity.

Many-to-many relationships are more common than one-to-one relationships. In these relationships, there is often some data we want to capture about the relationship. For example, take a look at the earlier version of our data model in Figure 2-8 that had the many-to-many relationship between Artist and CD. What data might we want to capture about that relationship? An Artist has a relationship with a CD because an Artist has one or more Songs on that CD. The data model in Figure 2-9 is actually another representation of this many-to-many relationship.

All many-to-many relationships should be resolved using the following technique:

1. Create a new entity (sometimes referred to as a junction entity). Name it appropriately. If you cannot think of an appropriate name for the junction entity, name it by combining the names of the two related entities (e.g., ArtistCD). In our data model, Song is a junction entity for the Artist-CD relationship.

2. Relate the new entity to the two original entities. Each of the original entities should have a one-to-many relationship with the junction entity.

3. If the new entity does not have an obvious unique identifier, inherit the identifying attributes from the original entities into the junction entity and make them together the unique identifier for the new entity.

In almost all cases, you will find additional attributes that belong in the new junction entity. If not, the many-to-many relationship still needs to be resolved, otherwise you will have a problem translating your data model into a physical schema.

**More 2NF**

Our data model is still not in 2NF. The value of the Record Label attribute has only one value for each CD, but we see the same Record Label in multiple CDs. This situation is similar to the one we saw with Band Name. As with Band Name, this duplication indicates that Record Label should be part of its own entity. Each Record Label releases one or many CDs. Each CD is released by one and only one Record Label. Figure 2-10 models this relationship.

**Third Normal Form (3NF)**

An entity is said to be in the third normal form if it is already in 2NF and no nonidentifying attributes are dependent on any other nonidentifying attributes. Attributes that are dependent on other nonidentifying attributes are normalized by moving both the dependent attribute and the attribute on which it is dependent into a new entity.
A Logical Data Modeling Methodology

The values of State Name and State Abbreviation would conform to 1NF because they have only one value per record in the Record Label entity. The problem here is that State Name and State Abbreviation are dependent on each other. In other words, if we change the State Abbreviation for a particular Record Label—from MN to CA—we also have to change the State Name—from Minnesota to California. We would normalize this by creating a State entity with State Name and State Abbreviation attributes. Figure 2-12 shows how to relate this new entity to the Record Label entity.

Now that we are in 3NF, we can say that our data model is normalized. There are other normal forms which have some value from a database design standpoint, but these are beyond the scope of this book. For most design purposes, the third normal form is sufficient to guarantee a proper design.

A Logical Data Modeling Methodology

We now have a completed logical data model. Let's review the process we went through to get here.

1. Identify and model the entities.
2. Identify and model the relationships between the entities.
3. Identify and model the attributes.
4. Identify unique identifiers for each entity.

5. Normalize.

In practice, the process is rarely so linear. As shown in the example, it is often tempting and appropriate to jump around between entities, relationships, attributes, and unique identifiers. It is not as important that you follow a strict process as it is that you discover and capture all of the information necessary to correctly model the system.

The data model we created in this chapter is quite simple. We covered an approach to creating such a model which is in-line with the type and complexity of databases you are likely to encounter in developing MySQL or mSQL databases. We did not cover a whole host of design techniques and concepts that are not so important to small-scale database design, but these can be found in any text dedicated to database design.

**Physical Database Design**

What was the point in creating the logical data model? You want to create a database to store data about CDs. The data model is only an intermediate step along the way. Ultimately, you would like to end up with a MySQL or mSQL database where you can store data. How do you get there? Physical database design translates your logical data model into a set of SQL statements that define your MySQL or mSQL database.

Since MySQL and mSQL are relational database systems, it is relatively easy to translate from a logical data model, such as the one we described earlier, into a physical MySQL or mSQL database. Here are the rules for translation:

1. Entities become tables in the physical database.
2. Attributes become columns in the physical database. You have to choose an appropriate datatypes for each of the columns.
3. Unique identifiers become columns that are not allowed to have NULLs. These are called primary keys in the physical database. You may also choose to create a unique index on the identifiers to enforce uniqueness. For your purposes, mSQL does not have a concept of a primary key. It simply has unique indices. This issue does not apply to MySQL.
4. Relationships are modeled as foreign keys. We will cover this later.

If we apply these rules to our data model—minus the Record Label address information—we will end up with the physical database described in Table 2-2.

---

**Table 2-2: Physical Table Definitions for the CD Database**

<table>
<thead>
<tr>
<th>Table</th>
<th>Column</th>
<th>Datatype</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>CD</td>
<td>CDId</td>
<td>INT</td>
<td>primary key</td>
</tr>
<tr>
<td></td>
<td>CDtitle</td>
<td>TEXT(50)</td>
<td>primary key</td>
</tr>
<tr>
<td>Artist</td>
<td>ArtistId</td>
<td>INT</td>
<td>primary key</td>
</tr>
<tr>
<td></td>
<td>ArtistName</td>
<td>TEXT(50)</td>
<td>primary key</td>
</tr>
<tr>
<td>Song</td>
<td>SongId</td>
<td>INT</td>
<td>primary key</td>
</tr>
<tr>
<td></td>
<td>SongName</td>
<td>TEXT(50)</td>
<td>primary key</td>
</tr>
<tr>
<td>RecordLabel</td>
<td>RecordLabelid</td>
<td>INT</td>
<td>primary key</td>
</tr>
<tr>
<td></td>
<td>RecordLabelName</td>
<td>TEXT(50)</td>
<td>primary key</td>
</tr>
</tbody>
</table>

The first thing you may notice is that all of the spaces are gone from the entity names in our physical schema. This is because these names need to translate into SQL calls to create these tables. Table names should thus conform to SQL naming rules. Another thing to notice is that we made all primary keys of type INT. Because these attributes are complete inventions on our part, they can be of any indexable datatype. The fact that they are of type INT here is almost purely arbitrary. It is almost arbitrary because it is actually faster to search on numeric fields in many database engines and hence numeric fields make good primary keys. However, we could have chosen CDID as the type for the primary key fields and everything would work just fine. The bottom line is that this choice should be driven by your criteria for choosing identifiers.

The rest of the columns are set to be of type TEXT with a length of 50. This definition works for both MySQL and mSQL. For MySQL, however, VARCHAR would be a better choice but not important to this example. Picking the right datatype for columns is very important, but we will not dwell on it here since we have not yet covered the datatypes for MySQL and mSQL.

We now have a starting point for a physical schema. We haven't yet translated the relationships into the physical data model. As we discussed earlier, once you have refined your data model, you should have mostly 1-to-1 and 1-to-M relationships—the M-to-M relationships were resolved via junction tables. We model relationships by adding a foreign key to one of the tables involved in the relationship. A foreign key is the unique identifier or primary key of the table on the other side of the relationship.

---

* Later in this book, we will cover the datatypes supported by MySQL and mSQL. Each database engine has different rules about which datatypes can be indexable. Neither database, for example, allows indices to be created on whole TEXT fields. It would therefore be inappropriate to have a primary key column be of type TEXT.
Chapter 2: Database Design

The most common relationship is the 1-to-M relationship. This relationship is mapped by placing the primary key on the "one" side of the relationship into the table on the "many" side. In our example, this rule means that we need to do the following:

- Place a `RecordLabelId` column in the `CD` table.
- Place a `CDId` column in the `Song` table.
- Place an `ArtistId` column in the `Song` table.

Table 2-3 shows the new schema.

Table 2-3. The Physical Data Model for the CD Database

<table>
<thead>
<tr>
<th>Table</th>
<th>Column</th>
<th>Datatype</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>CD</td>
<td>CDId</td>
<td>INT</td>
<td>primary key</td>
</tr>
<tr>
<td></td>
<td>CDTitle</td>
<td>TEXT(50)</td>
<td></td>
</tr>
<tr>
<td></td>
<td>RecordLabelId</td>
<td>INT</td>
<td>foreign key</td>
</tr>
<tr>
<td>Artist</td>
<td>ArtistId</td>
<td>INT</td>
<td>primary key</td>
</tr>
<tr>
<td></td>
<td>ArtistName</td>
<td>TEXT(50)</td>
<td>primary key</td>
</tr>
<tr>
<td>Song</td>
<td>SongId</td>
<td>INT</td>
<td>foreign key</td>
</tr>
<tr>
<td></td>
<td>SongName</td>
<td>TEXT(50)</td>
<td>foreign key</td>
</tr>
<tr>
<td></td>
<td>CDId</td>
<td>INT</td>
<td>foreign key</td>
</tr>
<tr>
<td></td>
<td>ArtistId</td>
<td>INT</td>
<td>primary key</td>
</tr>
<tr>
<td>RecordLabel</td>
<td>RecordLabelId</td>
<td>INT</td>
<td>primary key</td>
</tr>
<tr>
<td></td>
<td>RecordLabelName</td>
<td>TEXT(50)</td>
<td></td>
</tr>
</tbody>
</table>

We do not have any 1-to-1 relationships in this data model. If we did have such a relationship, it should be mapped by picking one of the tables and giving it a foreign key column that matches the primary key from the other table. In theory, it does not matter which table you choose, but practical considerations may dictate which column makes the most sense as a foreign key.

We now have a complete physical database schema ready to go. The last remaining task is to translate that schema into SQL. For each table in the schema, you write one `CREATE TABLE` statement. Typically, you will choose to create unique indices on the primary keys to enforce uniqueness.

We are, in a sense, jumping ahead at this point. You may not be familiar with SQL yet, and it is not the purpose of this chapter to introduce the MySQL and mSQL variants of SQL. Nevertheless, here are two sample scripts to create the CD database. The first script, Example 2-1, is for MySQL. Example 2-2 is for mSQL.

Example 2-1. An Example Script for Creating the CD Database in MySQL

```sql
CREATE TABLE CD (
    CD_ID INT NOT NULL,
    RECORDLABEL_ID INT,
    CD_TITLE TEXT,
    PRIMARY KEY (CD_ID))
CREATE TABLE Artist (ARTIST_ID INT NOT NULL,
    ARTIST_NAME TEXT,
    PRIMARY KEY (ARTIST_ID))
CREATE TABLE Song (SONG_ID INT NOT NULL,
    CD_ID INT,
    SONG_NAME TEXT,
    PRIMARY KEY (SONG_ID))
CREATE TABLE RecordLabel (RECORDLABEL_ID INT NOT NULL,
    RECORDLABEL_NAME TEXT,
    PRIMARY KEY (RECORDLABEL_ID))
```

Example 2-2. An Example Script for Creating the CD Database in mSQL

```sql
CREATE TABLE CD (CD_ID INT NOT NULL,
    RECORDLABEL_ID INT,
    CD_TITLE TEXT(50))
CREATE UNIQUE INDEX CD_IDX ON CD (CD_ID)
CREATE TABLE Artist (ARTIST_ID INT NOT NULL,
    ARTIST_NAME TEXT(50))
CREATE UNIQUE INDEX Artist_IDX ON Artist (ARTIST_ID)
CREATE TABLE Song (SONG_ID INT NOT NULL,
    CD_ID INT,
    SONG_NAME TEXT(50))
CREATE UNIQUE INDEX Song_IDX ON Song (SONG_ID)
CREATE TABLE RecordLabel (RECORDLABEL_ID INT NOT NULL,
    RECORDLABEL_NAME TEXT(50))
CREATE UNIQUE INDEX RecordLabel_IDX ON RecordLabel(RECORDLABEL_ID)
```

Data models are meant to be database independent. You can therefore take the techniques and the data model we have generated in this chapter and apply them not only to MySQL and mSQL, but to Oracle, Sybase, Ingres, or any other relational database engine. In the following chapters, we will discuss the details of how you can merge your new database design knowledge into MySQL and mSQL.
